

Introduction to C++

Data Abstraction w/ Classes

Topic #3

Topic #3

- **Abstract Data Types**

- Introduction to...Object Models
- Introduction to...Data Abstraction
- Using Data Abstraction in C++ ...an introduction to the class

- **Members of a Class**

- The class interface, using the class, the class interface versus implementation
- Classes versus Structures
- Constructors, Destructors
- Dynamic Memory and Linked Lists

Programming Paradigms

- The most important aspect of C++ is its ability to support many different programming paradigms
 - procedural abstraction
 - modular abstraction
 - data abstraction
 - object oriented programming (this is discussed later, in CS202)

Procedural Abstraction

- This is where you build a “fence” around program segments, preventing some parts of the program from “seeing” how tasks are being accomplished.
- Any use of globals causes side effects that may not be predictable, reducing the viability of procedural abstraction

Modular Abstraction

- With modular abstraction, we build a “screen” surrounding the internal structure of our program prohibiting programmers from accessing the data except through specified functions.
- Many times data structures (e.g., structures) common to a module are placed in a header files along with prototypes (allows external references)

Modular Abstraction

- The corresponding functions that manipulate the data are then placed in an implementation file.
- Modules (files) can be compiled separately, allowing users access only to the object (.o) files
- We progress one small step toward OOP by thinking about the actions that need to take place on data.

Modular Abstraction

- We implement modular abstraction by separating out various functions/structures/classes into multiple .cpp and .h files.
- .cpp files contain the implementation of our functions
- .h files contain the prototypes, class and structure definitions.

Modular Abstraction

- We then include the .h files in modules that need access to the prototypes, structures, or class declarations:
 - `#include “myfile.h”`
 - (Notice the double quotes!)
- We then compile programs (on UNIX) by:
 - `g++ main.cpp myfile.cpp`
 - (Notice no .h file is listed on the above line)

Data Abstraction

- Data Abstraction is one of the most powerful programming paradigms
- It allows us to create our own user defined data types (using the class construct) and
 - then define variables (i.e., objects) of those new data types.

Data Abstraction

- With data abstraction we think about what operations can be performed on a particular type of data and not how it does it
- Here we are one step closer to object oriented programming

Data Abstraction

- Data abstraction is used as a tool to increase the modularity of a program
- It is used to build walls between a program and its data structures
 - what is a data structure?
 - talk about some examples of data structures
- We use it to build new abstract data types

Data Abstraction

- An abstract data type (ADT) is a data type that we create
 - consists of data and operations that can be performed on that data
- Think about a `char` type
 - it consists of 1 byte of memory and operations such as assignment, input, output, arithmetic operations can be performed on the data

Data Abstraction

- An abstract data type is any type you want to add to the language over and above the fundamental types
- For example, you might want to add a new type called: list
 - which maintains a list of data
 - the data structure might be an array of structures
 - operations might be to add to, remove, display all, display some items in the list

Data Abstraction

- Once defined, we can create lists without worrying about how the data is stored
- We “hide” the data structure used for the data within the data type -- so it is transparent to the program using the data type
- We call the program using this new data type: the client program (or client)

Data Abstraction

- Once we have defined what data and operations make sense for a new data type, we can define them using the class construct in C++
- Once you have defined a class, you can create as many instances of that class as you want
- Each “instance” of the class is considered to be an “object” (variable)

Data Abstraction

- Think of a class as similar to a data type
 - and an object as a variable
- And, just as we can have zero or more variables of any data type...
 - we can have zero or more objects of a class!
- Then, we can perform operations on an object in the same way that we can access members of a struct...

What is a Class?

- Remember, we used a structure to group different types of data together under a common name
- With a class, we can go the next step and actually define a new data type
- In reality, structures and classes are 100% the same except for the default conditions
 - everything you can do with a class you can do with a structure!

What is a Class?

- First, let's talk about some terminology
 - Think of a class as the same as a data type
 - Think of an object as the same as a variable
- An “object” is an instance of a class
 - Just like a “variable” is an instance of a specific data type
- We can zero or more variables (or objects) in our programs

When do we used Classes?

- I recommend using structures when you want to group different types of data together
 - and, to use a class when we are interested in building a new type of data into the language itself
 - to do this, I always recommend forming that data type such that it behaves in a consistently to how the fundamental data types work

But, What is a Data Type?

- We've been working with fundamental data types this term, such as ints, floats, chars...
- Whenever we define variables of these types,
 - memory is allocated to hold the data
 - a set of operations can now be performed on that data
 - different data types have different sets of operations that make sense (the mod operator doesn't make sense for floats...)

Defining new Data Types...

- Therefore, when we define a new data type with the class construct
 - we need to specify how much memory should be set aside for each variable (or object) of this type
 - and, we need to specify which operations make sense for this type of data (and then implement them!!)
 - and, what operators makes sense (do be discussed with **operator overloading**)

Defining a Class...

- Once we have decided on how the new type of data should behave, we are ready to define a class:

```
class data_type_name {  
    public:  
        //operations go here  
    private:  
        //memory is reserved here  
};
```

For Example, here is a Class Interface

```
class string {  
    public:  
        string();  
        int copy(char []);  
        int length();  
        int display();  
    private:  
        char str[20];  
        int len;  
};
```

Then, the Class Implementation

```
string::string() {  
    str[0]='\0';          len = 0;  
}  
  
int string::copy(char s []) {  
    if (strlen(s) < 20)  
        strcpy (str, s);  
    else {  
        for (int i = 0; i < 20; ++i)  
            str[i] = s[i];  
        str[20]='\0';  
    }  
    len = strlen(str); return len;  
}
```

More of the Class Implementation

```
int string::length() {  
    return len;  
}  
int string::display() {  
    cout <<str;  
    return len;  
}
```

Defining Objects of this Class

- Notice how similar defining objects of class is to defining variables of any data type:

`string my_str; vs. int i;`

- Defining an object causes the “constructor” to be invoked; a constructor is the same named function as the class (string) and is used to initialize the memory set aside for this object
- Think about how much memory is set aside?
- What initial values should it take on?

Using Objects of this Class

- Think about how you can use those objects

```
my_str.copy("hi!");  
cout << my_str.length();
```

- We are limited to using only those operations that are defined within the public section of the class interface
- The only “built-in” operation that can be used with objects of a class is the assignment operation, which does a memberwise copy (as we learned with structures)

Using Objects of this Class

- Notice how similar the use of these operations is to the `cin.get` function.....

```
cin.get(ch) ;
```

- This should be a clue. `cin` therefore is an object of the `istream` class.
- The dot is the member access operator; it allows us to access a particular public member function defined within the `istream` class.
- The function `get` is therefore defined within the public section of the `istream` class

Limitations...

- But, there are limitations!
- If our goal is to really be able to use my string objects in a way consistent with the fundamental data types,
 - then I would expect to be able to read strings using the extraction operator
 - and to display strings by directly using the insertion operator
 - and to concatenate strings using +

Limitations...

- With the class as it is defined, none of these things can be done...
 - the only operations that can be performed are those specified within the public section of the class interface, and a memberwise copy with the assignment operator
 - No other operations are known
- Therefore, to be consistent, we must revise our class to use operator overloading

For Example, here is a Class Interface

```
class string {  
    public:  
        string();  
        int length();  
    friend ostream & operator <<  
        (ostream &, const string &);  
    friend ifstream & operator >>  
        (ifstream &, string &);  
    private:  
        char str[20];  
        int len;  
};
```

List Example

- For a list of videos, we might start with a struct defining what a video is:

```
struct video {  
    char title[100];  
    char category[5];  
    int quantity;  
};
```

We will re-visit this example using dynamic memory once we understand the mechanics of classes

List Example

- For a list of videos data type:

```
class list {  
    public:  
        list();  
        int add (const video &);  
        int remove (char title[]);  
        int display_all();  
    private:  
        video my_list[CONST_SIZE];    //for now...  
        int num_of_videos;  
};
```

List Example

- For a client to create a list object:

```
int main() {  
    list home_videos;      //has an array of 100  
    videos  
    list kids_shows;      //another 100 videos  
    here...  
  
    ...  
  
    video out_of_site;  
    cin.get(out_of_site.title,100,'\n');  
    cin.ignore(100,'\n');  
    ...  
  
    home_videos.add(out_of_site);      //use  
    operation                          CS162 Topic #3
```

Introduction to C++

Data Hiding and Member Functions

Data Abstraction in C++

- Terminology
- Data Hiding
- Class Constructors
- Defining and using functions in classes
- Where to place the class interface and implementation of the member functions

“class” Terminology

- Class
 - think data type
- Object
 - instance of a class, e.g., variable
- Members
 - like structures, the data and functions declared in a class
 - called “data members” and “member functions”

“class” Terminology

- A class could be a list, a string, a counter, a clock, a bank account, etc.
 - discuss a simple counter class on the board
- An object is as real as a variable, and gets allocated and deallocated just like variables
 - discuss the similarities of:

```
int i;
```

```
list j;
```

“class” Terminology

- For the list of videos data type we used

```
class list {      <--- the data type!!!  
    public:  
        list();    <--- the constructor  
        int add (const video &); ← 3 member functions  
        int remove (char title[]); ←  
        int display_all(); ←  
    private:  
        video my_list[CONST_SIZE]; ← data members  
        int num_of_videos; ←  
}; <--- notice like structures we need a semicolon
```

“class” Terminology

- If we examine the previous class,
 - notice that classes are really very similar to structures
 - a class is simply a generalized structure
 - in fact, even though we may not have used structures in this way...

Structures and Classes are 100% identical except for their default conditions...

- by default, all members in a structure are available for use by clients (e.g., main programs); they are public

“class” Terminology

- We have seen the use of structures in a more simple context,
 - as we examined with the **video** struct.
- It had three members (data members)
 - called title, category, and quantity.
- They are “public” by default,
 - so all functions that have objects of type video can directly access members by:

video object;

object.title

object.category

object.quantity

“class” Terminology

- This limited use of a structure was appropriate, because
 - it served the purpose of grouping different types of data together as a single unit
 - so, anytime we want to access a particular video -
 - we get all of the information pertaining to the video all at once

Structure Example

- Remember, anything you can do in a struct you can do in a class.
 - It is up to your personal style how many structures versus classes you use to solve a problem.
- Benefit: Using structures for simple “groupings” is compatible with C

```
struct video {  
    char title[100];  
    char category[5];  
    int quantity;  
};
```

“class” Terminology

- To accomplish data hiding and encapsulation
 - we usually turn towards classes
- What is data hiding?
 - It is the ability to protect data from unauthorized use
 - Notice, with the video structure, any code that has an object of the structure can access or modify the title or other members

Data Hiding

- With data hiding
 - accessing the data is restricted to authorized functions
 - “clients” (e.g., main program) can’t muck with the data directly
 - this is done by placing the **data members** in the private section
 - and, placing **member functions** to access & modify that data in the public section

Data Hiding

- So, the public section
 - includes the data and operations that are visible, accessible, and useable by all of the clients that have objects of this class
 - this means that the information in the public section is “transparent”; therefore, all of the data and operations are accessible outside the scope of this class
 - by default, nothing in a class is public!

Data Hiding

- The private section
 - includes the data and operations that are not visible to any other class or client
 - this means that the information in the private section is “opaque” and therefore is inaccessible outside the scope of this class
 - the client has no direct access to the data and must use the public member functions
 - this is where you should place all data to ensure the memory’s integrity

Data Hiding

- The good news is that
 - member functions defined in the public section can use, return, or modify the contents of any of the data members, directly
 - it is best to assume that member functions are the only way to work with private data
 - (there are “friends” but don’t use them this term)
 - Think of the member functions and private data as working together as a team

“class” Terminology

- Let’s see how “display_all” can access the data members:

```
class list {  
    public: ← notice it is public  
        int display_all() {  
            for (int i=0; i<num_of_videos; ++i)  
                cout <<my_list[i].title <<'\t'  
                    <<my_list[i].category  
                    <<'\t' <<my_list[i].quantity <<endl;  
        }  
    ...  
    private:  
        video my_list[CONST_SIZE];  
        int num_of_videos;  
};
```

Data Hiding

- Notice, that the `display_all` function can access the private `my_list` and `num_of_videos` members, directly
 - without an object in front of them!!!
 - this is because the client calls the `display_all` function through an object
 - `object.display_all();`
 - so the object is implicitly available once we enter “class scope”

Where to place....

- In reality, the previous example was misleading. We don't place the implementation of functions with this class interface
- Instead, we place them in the class implementation, and separate this into its own file

Class Interface (.h)

- Class Interface: list.h

```
class list {  
    public:  
        int display_all()  
        ...  
    private:  
        video my_list[CONST_SIZE];  
        int num_of_videos;  
};
```

- list.h can contain:

- prototype statements
- structure declarations and definitions
- class interfaces and class declarations
- include other files

Class Implementation

- Class Implementation list.c

```
#include "list.h" ← notice the double quotes

int list::display_all() {
    for (int i=0; i<num_of_videos; ++i)
        cout <<my_list[i].title <<'\t'
            <<my_list[i].category
            <<'\t' <<my_list[i].quantity <<endl;
}
```

- Notice, the code is the same
- But, the function is prefaced with the class name and the scope resolution operator!
- This places the function in class scope even though it is implemented in another file
- Including the list.h file is a “must”

Constructors

- Remember that when you define a local variable in C++, the memory is not automatically initialized for you
- This could be a problem with classes and objects
- If we define an object of our list class, we really need the “num_of_videos” data member to have the value *zero*
- *Uninitialized just wouldn't work!*

Constructors

- Luckily, with a constructor we can write a function to initialize our data members
 - and have it implicitly be invoked whenever a client creates an object of the class
- The constructor is a strange function, as it has the same name as the class, and no return type (at all...not even void).

Constructor

- The list constructor was: (list.h)

```
class list {  
    public:  
        list();    <--- the constructor  
        ...  
};
```

- The implementation is: (list.cpp)

```
list::list() {  
    num_of_videos = 0;  
}
```

Constructor

- The constructor is implicitly invoked when an object of the class is formed:

```
int main() {
```

```
    list fun_videos;           implicitly calls the  
                                constructor
```

```
    list all_videos[10];      implicitly calls the  
                                constructor 10 times for  
                                each of the 10 objects!!
```

Dynamic Memory w/ Classes

- But, what if we didn't want to waste memory for the title (100 characters may be way too big (Big, with Tom Hanks))
- So, let's change our video structure to include a dynamically allocated array:

```
struct video {  
    char * title;  
    char category[5];  
    int quantity;  
};
```

Dynamic Memory w/ Classes

- Let's write a class that now allocates this list of videos dynamically, at run time
- This way, we can wait until we run our program to find out how much memory should be allocated for our video array

Dynamic Memory w/ Classes

- What changes in this case are the data members:

```
class list {  
    public:  
        list();  
        int add (const video &);  
        int remove (char title[]);  
        int display_all();  
    private:  
        video *my_list;  
        int video_list_size;  
        int num_of_videos;  
};
```

Replace the array
with these

Default Constructor

- Now, let's think about the implementation.
- First, what should the constructor do?
 - initialize the data members

```
list::list() {  
    my_list = NULL;  
    video_list_size = 0;  
    num_of_videos = 0;  
}
```

Another Constructor

- Remember function overloading? We can have the same named function occur (in the same scope) if the argument lists are unique.
- So, we can have another constructor take in a value as an argument of the number of videos
 - and go ahead and allocate the memory, so that subsequent functions can use the array

2nd Constructor

```
list::list(int size) {  
    my_list = new video [size];  
    video_list_size = size;  
    num_of_videos = 0;  
}
```

Notice, unlike arrays of characters, we don't need to add one for the terminating nul!

Clients creating objects

- The client can cause this 2nd constructor to be invoked by defining objects with initial values

```
list fun_videos(20); //size is 20
```

If a size isn't supplied, then no memory is allocated and nothing can be stored in the array....

Default Arguments

- To fix this problem, we can merge the two constructors and replace them with a single constructor:

```
list::list(int size=100) {  
    my_list = new video [size];  
    video_list_size = size;  
    num_of_videos = 0;  
}
```

(Remember, to change the prototype
for the constructor in the class
interface)

Destructor

- Then, we can deallocate the memory when the lifetime of a list object is over
- When is that?
- Luckily, when the client's object of the list class lifetime is over (at the end of the block in which it is defined) -- the **destructor** is implicitly invoked

Destructor

- So, all we have to do is write a destructor to deallocate our dynamic memory.

```
list::~~list() {  
    delete [] my_list;  
    my_list = NULL;  
    ...  
}
```

(Notice the ~ in front of the function name)

(It can take NO arguments and has NO return type)

(This too must be in the class interface....)

Review of Classes

- What is the difference between a class and a struct
- What is a data member?
- Where should a data member be placed in a class? (what section)
- What is a member function?
- Where should member functions be placed, if clients should use them?

Review of Classes

- What is the difference between a member function and a regular-old C++ function?
- What is the purpose of the constructor?
- Why is it important to implement a constructor?
- What is the difference between a class and an object?

Review of Classes

- Show an example of how a client program defines an object of a list class
- How then would the client program call the constructor? (trick question!)
- How then would the client program call the display_all function?
- Why are parens needed?

Review of Classes

- Write a simple class interface (called `number`) that has the following members:
 - an integer private data member (containing a `value`)
 - a constructor
 - a `set` member function, that takes an integer as an argument and returns nothing
 - a `display` member function

Review of Classes

- Now, let's try our hand at implementing these functions
 - a constructor
 - a `set` member function, that takes an integer as an argument and returns nothing
 - a `display` member function

Review of Classes

- What happens if we forgot to put the keyword `public` in the previous class interface?
- Why is it necessary to place the class name, followed by the scope resolution operator (`::`) when we implement a member function outside of a class?
